Abundance and Distribution of Inshore Benthic Fauna off Southwestern Long Island, N.Y.¹

FRANK W. STEIMLE, JR.² and RICHARD B. STONE³

ABSTRACT

This paper describes a qualitative and quantitative census of the inshore benthic fauna off southwest Long Island over the period February 1966 through January 1967, prior to construction of an ocean sewer outfall in the general vicinity. Preliminary analyses of data indicate the presence of three distinct communities: 1) an inshore medium to coarse grain sand community dominated by the bivalve, *Tellina agilis*, the amphipod, *Protohaustorius deichmannae*, and the echinoderm, *Echinarachnius parma*; 2) an offshore silty fine sand community dominated by the bivalve, *Nucula proxima*, and the polychaete, *Nephtys incisa*; and 3) a community dominated by the blue mussel, *Mytilus edulis*.

INTRODUCTION

In 1966, the Sandy Hook Laboratory, Middle Atlantic Coastal Fisheries Center, made a census of the benthic fauna off the southwest coast of Long Island. The objective was to collect quantitative and qualitative data on benthic biota in an attempt to evaluate the extent of existing pollution and to provide baseline data that could be used to determine effects of future domestic waste disposal in these waters (Stone and Steimle, 1966).

One method to study the effects of pollution in the aquatic environment is to investigate changes in benthic faunal species composition, distribution, and numbers. Reish (1957, 1959, 1960), Filice (1959), and Kitamori, Kobayashi, and Nagota (1959) stressed the importance of bottom-dwelling organisms to the study of water quality in the marine environment. Marine benthic populations, especially polychaetes (Reish, 1970) and amphipods (J. B. Pearce, National Marine Fisheries Service, Sandy Hook Laboratory, Highlands, N.J., pers. comm., 1972), have shown to be altered in the vicinity of a pollution source, e.g., domestic sewer outfall. This alteration may be evident as a change in community composition and species abundance.

In this paper, we present a preliminary analysis of data, which includes 11 cruises of the RV *Challenger* over transects from Rockaway Inlet to Fire Island during the period February 1966 through January 1967. The data analyzed are derived from 423 grab collections of benthic and epibenthic fauna. This study represents the first such benthic census in this part of the New York Bight, although work has been done in adjacent estuaries (Townes, 1939).

METHODS

We established 39 sampling stations along seven transects normal to the adjacent beach (Fig. 1). The transects ranged over proposed sewage outfall locations near Jones Inlet, Long Island, N.Y. Each transect began at a point as near shore as water depths and surf conditions would normally allow the *Challenger* to enter and extended seaward from 7.4 to 11.1 km. We spaced the sampling stations at 1.8 km intervals along the seven transects, except for Station D1, which was moved east 0.5 km because of a dangerous shoal. Station depths ranged from 4.9 to 25.2 m. Station coordinates are given to the nearest 0.1 nautical mile in Appendix Table 1.

Each station was sampled once a month from February 1966 through January 1967, except the December 1966 cruise which was cancelled because of adverse weather conditions. The interval between starting dates was 30 days and all stations were sampled within 5 days.

¹ This survey was funded by Manganaro, Martin and Lincoln, Consulting Engineers, New York, N.Y.

² Sandy Hook Laboratory, Middle Atlantic Coastal Fisheries Center, NMFS, NOAA, Highlands, NJ 07732.

³ Atlantic Estuarine Fisheries Center, National Marine Fisheries Service, NOAA, Beaufort, NC 28516.

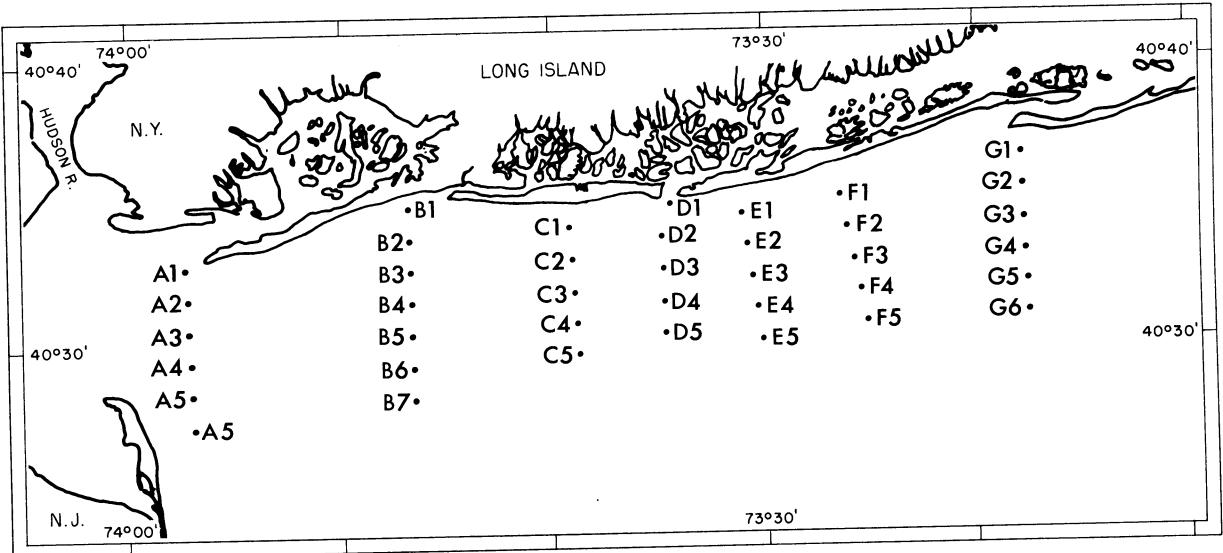

Figure 1.—RV *Challenger* survey, 1966-67. Locations of transects and collecting stations. Station D-1 is at the mouth of Jones' Inlet.

We used a 0.0624 m² Petersen grab (Fig. 2) to collect samples at each station. Each sample was washed through two screens, with 2- and 1-mm mesh openings. All organisms collected on both screens were stored together in a jar and fixed with 10% Formalin buffered with borax. Later the samples were transferred to 70% ethanol for permanent preservation.

Loran navigation was the principal method used for positioning the *Challenger* on collecting stations. We increased accuracy when possible, by use of radar, land ranges, and by visual sightings of buoys and light towers.

After primary sorting into major phyletic groups, each sample was processed separately and organisms identified to species, whenever possible, and counted. The responsibility of species identification was assumed by the senior author with the aid of authorities listed in the acknowledgment. Alpine Geophysical Associates, Inc., Norwood, N.J., analyzed sediments collected at each station during the period June through September.

RESULTS

Hydrography

Monthly mean values (bottom and surface) for water temperatures, salinity, and dissolved oxygen for the survey transects, available for the period

February to November 1966 (Alpine Geophysical Associates, 1967) are nearly constant on all transects with the exception of salinity values on A transect. Mean bottom water temperature ranged seasonally from a minimum of 1.5°C in February to a maximum of 20.0°C in September and declined to 11.1°C in November. The salinity near the bottom was generally uniform east of Rockaway Inlet, ranging from 31.0 to 32.3‰ during the 10-mo survey. Bottom salinities obtained from the far western part of the survey area, including A transect (near the mouth of the Hudson River), were consistently lower and fluctuated from month to month; bottom salinity there ranged from 27.3 to 31.2‰ during the 10 mo sampled. Dissolved oxygen values of the bottom water ranged from a high of 7.5 ppm (parts per million) in February to a low of 4.2 ppm in July, then rising slowly to 5.6 ppm in November. The dissolved oxygen values for the western transects were generally lower than those of the eastern portion during the summer months, July and August, with a low value of 3.5 ppm found on Transect A during July.

Sediments

Analysis showed a predominantly medium to coarse sand bottom at most stations with the exception of Transect B where all of the stations were characterized by finer sediments (Appendix Table 2).

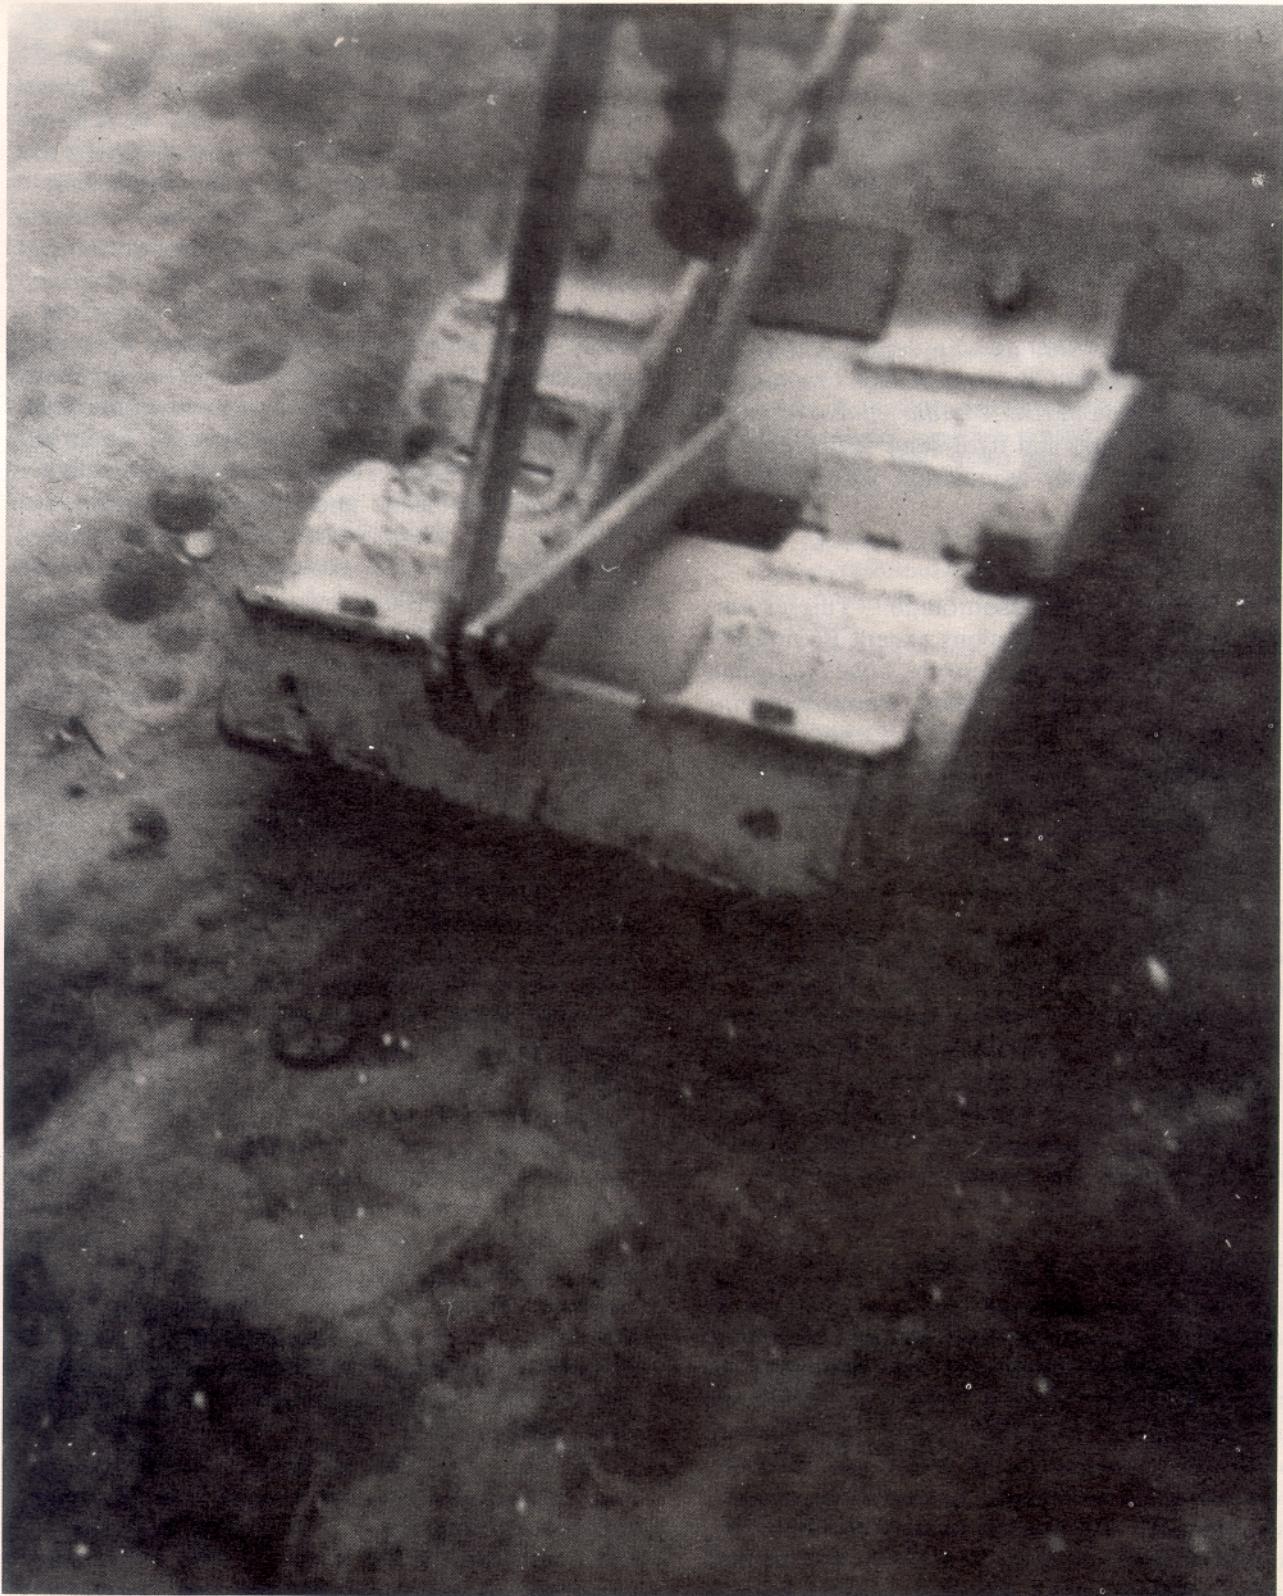

Figure 2.—The Petersen grab sampling a medium sand bottom station; sand dollars, *Echinarchnius parma*, are evident on surface.

Biota

We recorded 145 invertebrate species representing nine phyla in the study area (Appendix Table 3). Our preliminary analysis of the species composition at all stations (Appendix Table 4) indicates that the benthic fauna in the survey area can be separated into at least two distinct assemblages. Two of these assemblages show a strong association with sediment types (medium to coarse sand and fine sand mixed with silt) as well as with depth. A third assemblage dominated by apparently unattached clumps of the blue mussel, *Mytilus edulis*, was collected on both mud and hard sand sediments and showed no particular association with sediment type.

The medium sand assemblage.—This assemblage was found at all stations except B6 and B7. The dominant organisms were the bivalve, *Tellina agilis*; the burrowing amphipod, *Protohaustorius deichmannae*; the sand dollar, *Echinarachnus parma*; the tube-dwelling amphipod, *Unciola irrorata*; and the surf clam, *Spisula solidissima*. Other invertebrates commonly collected as part of this assemblage were the cumacean, *Leptocuma minor*; the amphipods, *Acanthohaustorius millsi*, *Trichophoxus epistomus*, and *Monoculodes edwardsi*; and the polychaetes, *Sthenelais limicola*, *Lumbrineris fragilis*, and *Spiophanes bombyx*.

The mean number of organisms collected from the medium sand sediment ranged from 49 animals/m², Station E1, to 2,030 animals/m², Station E3 (Appendix Table 5). The total number of species generally increased with depth from a low of 11 at Station E1 to a high of 54 at Station D5 (Appendix Table 5).

The fine silty sand assemblage.—This assemblage was evident offshore mainly at Stations B6 and B7 and occasionally at the offshore stations of the D, E, and G transects. The dominant organisms were the bivalve, *Nucula proxima*, and the polychaete, *Nephtys incisa*, with other polychaetes, *Pherusa affinis* and *Clymenella torquata*, and the amphipod, *Leptocheirus pinguis*, also abundant. The average density at Station B7, the only station not transitional with the medium sand assemblage, was 1,440 animals/m² (Appendix Table 5). A total of 50 species were collected from this station (Appendix Table 5).

Aggregations of *Mytilus edulis*.—Clumps of blue mussels unattached to a substratum, were found on Stations A1, A2, and A5 during June through September (Appendix Table 4). These clumps consisted of variable size mussels from 1 to 5 cm in length; the 1-cm-size group included approximately 95% of all individuals. These clumps were situated on a medium to coarse sand bottom; a solid substrate, usually necessary for *Mytilus* attachment and development, was absent. Commonly found within the *Mytilus* clumps were the polychaetes, *Harmothoe extenuata*, *H. imbricata*, *Nereis succinea*, and *Lepidonotus squamatus*. The brachyuran crab, *Neopanope texana*, and the anemone, *Metridium senile*, were also abundant. The fauna in the sand underlying the clumps was typical of the *Tellina-Protohaustorius-Echinarachnus* medium-sand assemblage. Where these clumps originated is unknown. They may have been broken away by storm surges from mussel beds that are known to be nearby. It is possible that our sampling in the spring and fall missed the clumps which are present throughout the year.

DISCUSSION

It is apparent from Appendix Tables 4 and 5 that the relative abundance and diversity of species vary. In general, an increase in total numbers of species collected per station is directly related to an increase in water depth. For example, the average total number of species collected on the 11 stations in less than 10 m in depth was 20.8 species, on the 21 stations between 10 and 20 m, the average total was 27.9 species, and on the 7 stations in water greater than 20 m the average total was 45.7 species. No correlation between total number of organisms collected and depth could be detected. Many of the most abundant species appear to be distributed contagiously (Fager, 1966) on the bottom, especially: *Unciola irrorata*, *Echinarachnus parma*, *Spiophanes bombyx*, and *Spisula solidissima*. It is possible that this contagion is the result of inadequate sampling.

The fine silty sand assemblage, dominated by *Nucula proxima* and *Nephtys incisa*, is similar to the soft bottom community in Buzzards Bay, Mass., and Long Island Sound (Sanders, 1956, 1958). Sanders reported that *Nucula proxima* and *Nephtys incisa* made up 57% and 17% respectively of the total number of organisms collected in Buzzards Bay. At

Station B7, in this study, these species made up 47% and 10% respectively of the total number collected. The sediments at this station visibly contained large amounts of finer sediment material, silt, not measured in the sediment analysis.

Individual rock crabs, *Cancer irroratus*, were generally found infrequently throughout the survey area. During the summer, however, juveniles were collected in abundance throughout the study area. This can be attributed to the settling of larvae in June. The large numbers collected in July consisted principally of juveniles (0.5-1.5 cm carapace width). The number declined rapidly after July, probably due to predation by fish and other predators.

Of the organisms collected in lesser numbers two are of particular interest. Both of these are polychaetous annelids that have only been reported from areas far distant from the New York Bight. In April 1966, on Station C3, four specimens of *Pisidium* sp. were collected. This genus had previously been described from South African waters (M. Simpson, Adelphi University, Garden City, Long Island, N.Y., pers. comm., 1969). The second species was tentatively identified as *Magalone riojae*, previously known from Pacific waters (Simpson, pers. comm., 1969). This specimen was collected at Station D4 during the January 1967 cruise. Both species were sent to authorities at the Smithsonian Institution, Washington, D.C. for verification.

ACKNOWLEDGMENTS

We appreciate the cooperation of colleagues who assisted in the identification of benthic forms: Edward L. Bousfield, National Museum of Natural Sciences, Ottawa, Canada; and Margaret Simpson, Adelphi University, Garden City, Long Island, N.Y.
